20. ABSTRACT This report describes an improved model for producing line-of-sight maps. Many models determine whether a target is within view by drawing a terrain profile between observer and target and examining it to see if it interferes with line of sight; this requires generating a completely new profile for each target position. The new model avoids this time-consuming profile generation by dynamically recording the characteristics of a "running horizon" as computations are made for points further away from the observer. For each target point, a check is made to determine whether the target is behind the "horizon". This new approach results in a dramatic savings in both storage and computing time requirements.

SEEFAR: AN IMPROVED MODEL FOR PRODUCING LINE-OF-SIGHT-MAPS

1. INTRODUCTION

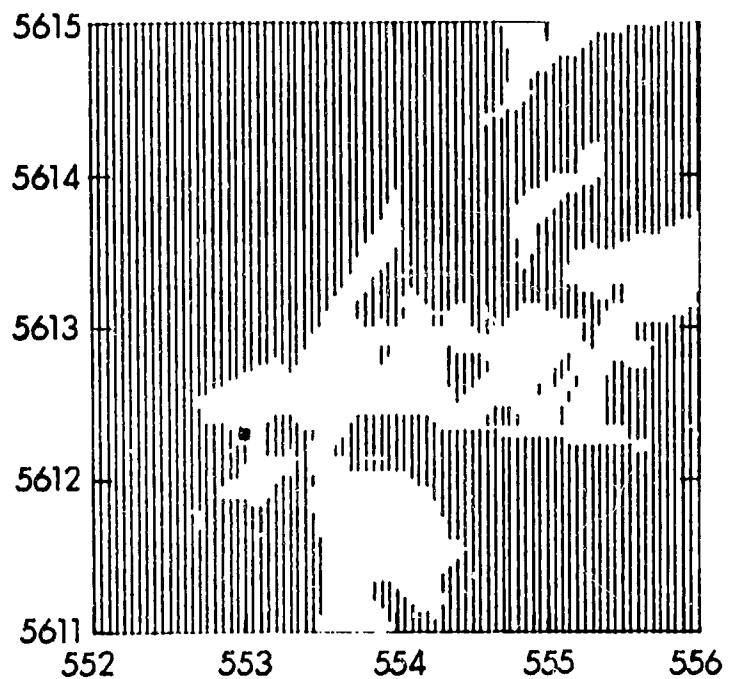

A line-of-sight map, or intervisibility plot, is a graphical representation of those portions of a geographical area which are visible to a given observer. (The term "visible" throughout this report refers to the existence of line of sight from an observation point to a target point which is uninterrupted by intervening terrain or obstacles.) These maps may be as shown in Figure 1, where the hatched portions represent those areas in which a target of a given height would be obscured. Targets in the blank portions would be visible. Or the maps may be shown as in Figure 2, where multiple target heights are considered. Each symbol plotted in a certain area indicates that targets of the associated height (or higher) located in this area are visible to the observer. For example, in Figure 2 a target 10 meters high (or higher) would be visible to the indicated observer if located at the point with UTM (Universal Transverse Mercator Projection) coordinates (554500, 5612600).

A number of computer programs are available for providing these maps; most of these programs are based on the algorithm described as "an intuitive approach" in this report. LOSMAP is one such program available at USAMSA. Use of an alternate algorithm, however, has resulted in a considerable reduction in both the memory requirements and compute time. An implementation of this algorithm, called SEEFAR, is included in Appendix A. The purpose of this report is to describe the basic SEEFAR algorithm and to compare it to the LOSMAP approach.

Line-of-sight maps have proved particularly useful in the development of combat scenarios for selecting reasonable observer positions and tactically sound attack routes. These maps can be useful to the wargamer, to the tactician in the field, and to the test plan developer. Additionally, they may be helpful in developing desirable weapon system characteristics. For example, it would be fruitless to develop a weapon system requiring line of sight with a range of 10 kilometers to be used in an area where observers typically cannot see a target at further than 5 kilometers.

The information required to produce these maps is of three types. First, the positional relationship between the map and observer must be specified. An area of interest is denoted by its extreme rectangular coordinates. The observer's position must be within this area. Secondly, heights of the observer and the target are required. The target height is the height of that point on the target that must be seen before the target is considered visible; the observer height designates the eye or sensor position above the ground. Finally, the actual terrain elevations along with any ancillary terrain data must be supplied.

The Defense Mapping Agency (DMA) digitized terrain data fulfill the third information requirement. These data were created by extracting elevations from contour lines on 1:50000 scale contour maps. Then, through planar interpolation, elevations were obtained at 12.5-meter intervals. This information

Multiple Target Height

is supplied on magnetic tapes as south-to-north strings of data sweeping from west to east. The term scanline, or scan, throughout this paper will denote a south-to-north string of information. Thus, the DMA data is a set of elevation scanlines. Additionally, an indication of the presence of a forest, orchard or urban area has been included with each elevation.

2. AN INTUITIVE LINE-OF-SIGHT ALGORITHM (LOSMAP)

2.1 Algorithm Description.

Now, given the information described in the previous section, suppose we wish to produce a map like that in Figure 1. Basically, at evenly spaced intervals throughout the area of interest the question must be asked, "Can the observer see the target if it is at this spot?" A reasonable approach to answering this question is to draw the terrain profile between the observer and the target, then draw the line from the observer eyeball to the target point and determine whether the terrain profile interrupts that observer-target line. If there is no interruption, line of sight exists; otherwise, this spot is not visible.

In Figure 3 the observer and target are depicted in the array of digitized elevations. As the figure indicates, at each point where the line between observer and target crosses a grid line, linear interpolation is used to find another height on the desired profile. As the profile is thus being constructed, a comparison is made between the elevation of each new point on the profile and the corresponding height of the line drawn from the observer eyeball to the target point. If the profile height is ever the larger of the two heights, line of sight does not exist; otherwise, line of sight does exit.

Of course this is a simplification of the problem. Because the presence of vegetation and urban areas can have a major impact on visibility for an observer, it is generally desirable to use the DMA vegetation/urban indicators. For example, while constructing the profile an appropriate height increment may be added to the profile if it runs through trees or towns. Further, the effect of earth curvature must be considered. If multiple target heights are considered, some accounting method must be used to keep track of the minimum visible target height. This brief description gives enough information to point out the major problems with the algorithm: computer space and time requirements.

2.2 Problems Encountered: Storage and Compute Time

As long as the area of interest is small, there is no problem. The use of high speed computers enables one to perform the required calculations with ease.

Notice, however, that this algorithm requires easy access to elevations in the entire area of interest. For each target point, an observer-to-target profile is constructed, requiring the elevations of many intervening points. Consider making a 6 x 6 kilometer map. If a 12.5-meter grid is used, an array of elevations dimensioned 481 x 481 is needed. Storing one elevation per word would require 231,361 words of memory for the elevation array alone! This problem can be somewhat alleviated by using a thinned grid of 25, 50 or even 100 meters. While this thinning may result in more inaccuracy, the outcome is often deemed adequate. Further, these elevations may be packed into the elevation array several at a time thereby decreasing the required storage even more. But, inevitably, as the size of the area that can be handled is increased, a problem is encountered that requires an area slightly larger. Some have solved the

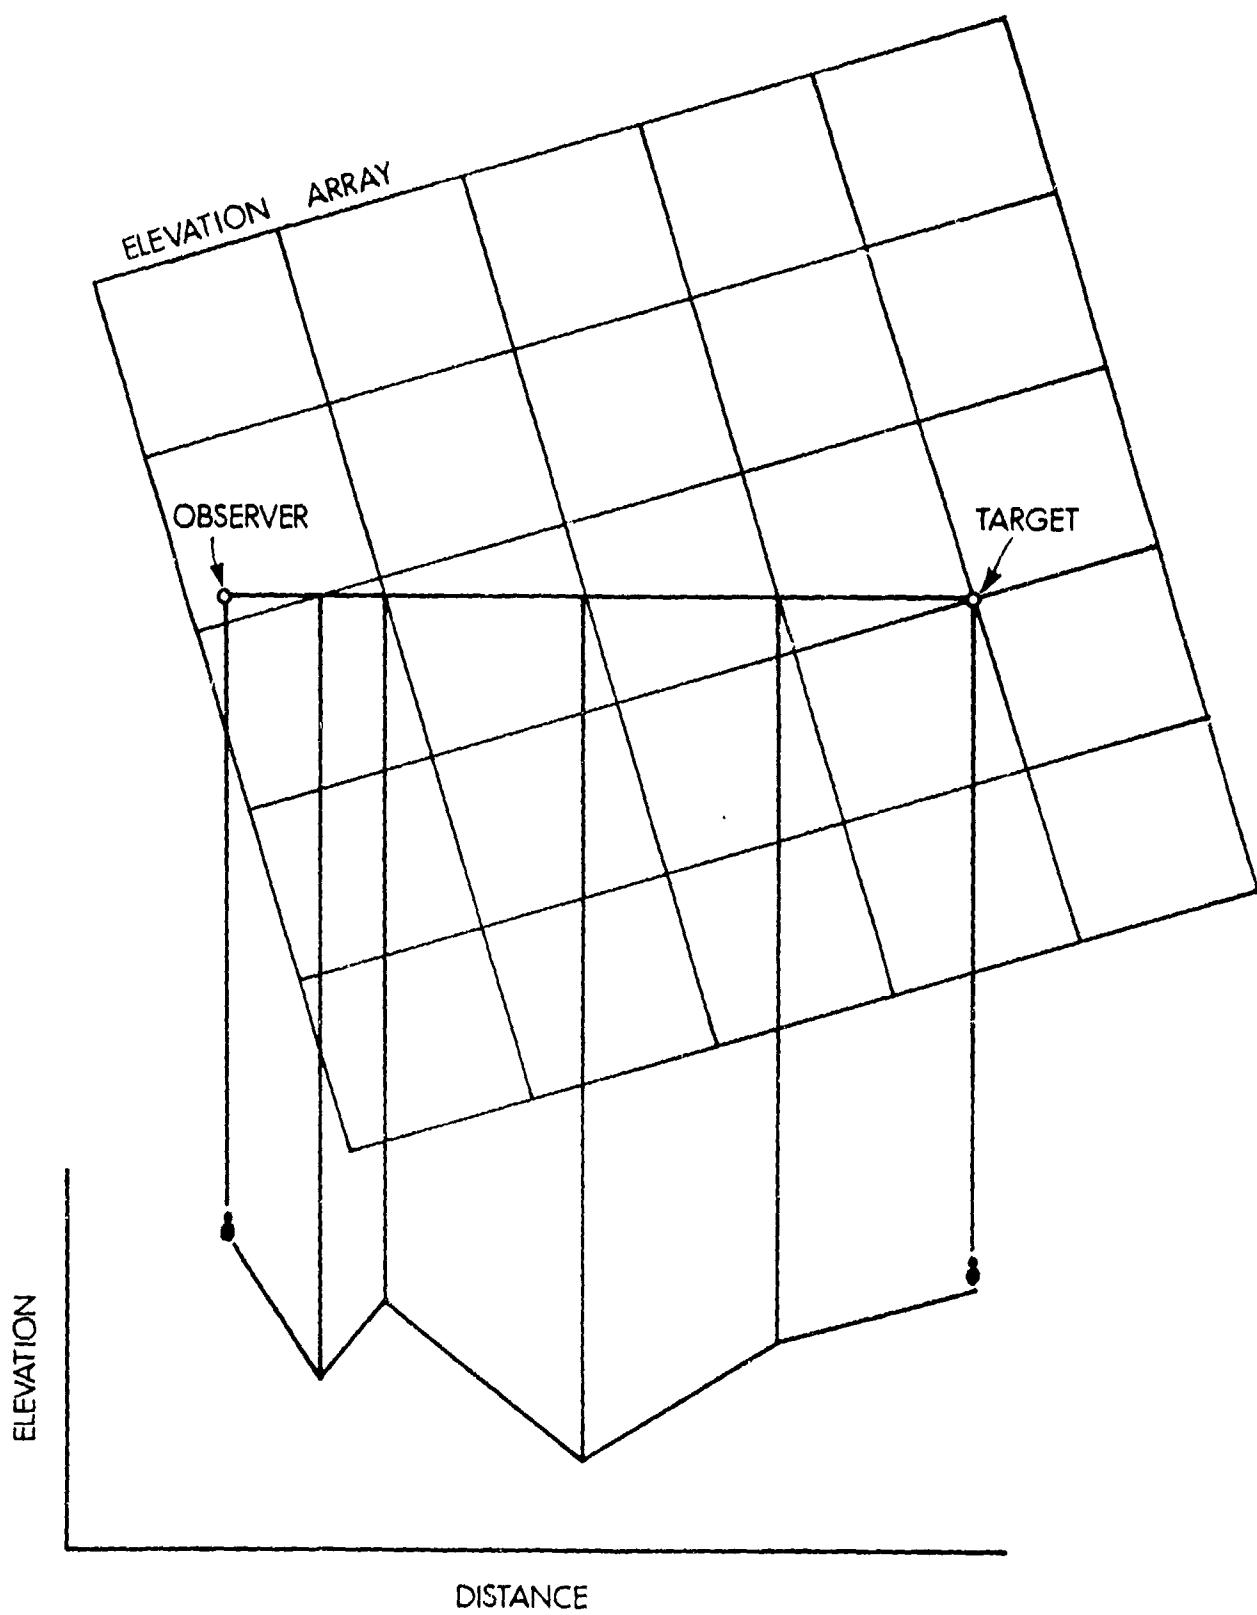

Figure 3. Constructing the Profile from Observer to Target.

storage problem by swapping data in and out of memory as needed. This, however, is rather cumbersome and will tremendously increase input-output time requirements. As one becomes concerned with larger areas of interest, as in air-to-ground and air-to-air intervisibility studies, this storage problem must be faced some other way.

Another problem to consider is that of compute time. If one needs a simple line-of-sight map like that in Figure 1, it is hard to predict exactly how many calculations will be performed. For each point on the map a profile must be started, so for an $n \times n$ map, at least n^2 calculations will be performed. If the profile interrupt is encountered early, few extra calculations will be needed. But, when line of sight to the target point exists, the entire profile must be constructed and each height comparison must be performed. With maps like that in Figure 2, considering multiple target heights, it becomes more likely that the entire profile must be constructed for every target point. The required number of calculations would then be of order n^3 (See Appendix C1). For large areas, this could easily be a prohibitively expensive algorithm.

3. DYNAMIC PROGRAMMING ALGORITHM (SEEFAR)

3.1 Algorithm Description.

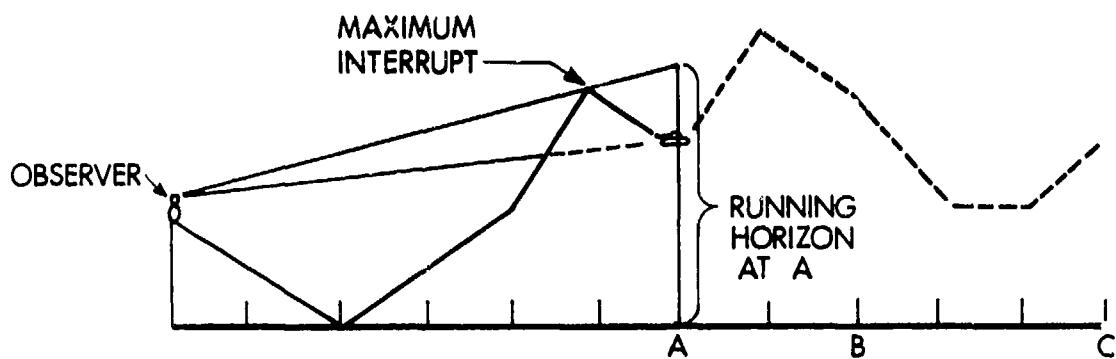

A. One Ray. Now consider an alternate approach to the development of line-of-sight maps. How should line-of-sight calculations be performed if all the target positions lay along one line? For each target position along the ray the question must be answered, "How high must the target be raised to be seen?" But it hardly seems necessary to draw a new profile for each target position. Instead, one might choose to work from the observer out, extending the profile to each new target position, not keeping track of all the previously encountered elevations but simply updating the effect of the maximum interrupt encountered thus far as new interrupts are encountered. This maximum interrupt effect projected to the current target position is essentially the minimum target height required to overcome the effect of terrain between the observer and the target. This height can be thought of as a running horizon, running in the sense that it must be updated as target positions move further from the observer.

For each target position, then, the following procedure could be followed:

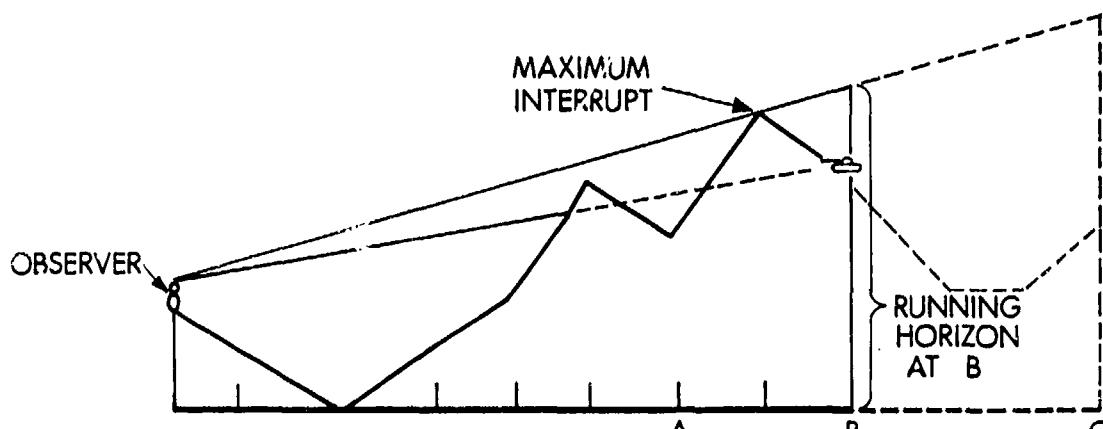

- (1) Check to see if the current target position is above or below the current horizon (i.e., in or out of view)
- (2) Plot the results
- (3) Update the running horizon to reflect its movement outward, and any greater interrupts encountered. (This new horizon value will be used in the line of sight calculation for the next target position.)

Consider now this running horizon, or maximum interrupt effect. Figure 4 demonstrates maximum interrupts, how they can change as the profile is extended, and how their corresponding projected effect must continually be updated. The maximum interrupt effect must be updated both as new interrupts are encountered and as the target position is changed. A comparison of Figures 4A and 4B demonstrates the need to update the running horizon as greater interrupts are encountered. Considering Figures 4B and 4C, it can be seen that the effect of the maximum interrupt will vary for different target positions even though the maximum itself may remain the same. One should further note that, as shown in Figure 5, the maximum interrupt is not necessarily the terrain profile with the highest elevation.

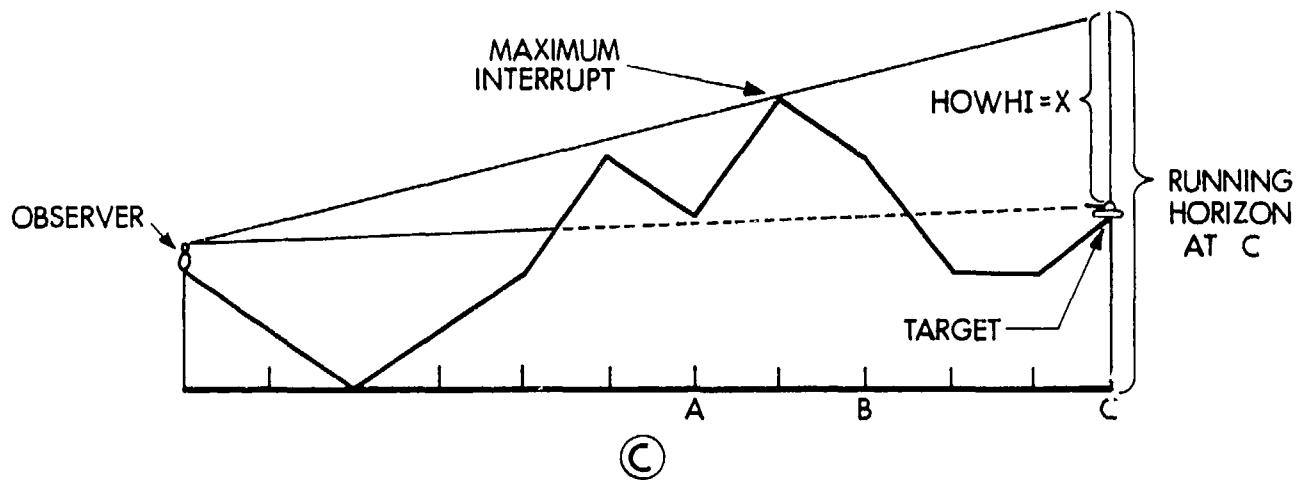

This procedure has several nice features. First, because it is not necessary to draw a new profile for each target position, fewer steps are required. Further, it is not necessary to store all the elevations between the observer and the target to determine whether line of sight exists. The elevation of the current target position and the horizon effect are the only values needed. This method can be extended to produce a full map, rather than a single ray, greatly reducing the storage and compute time problems.

(A)

(B)

(C)

Figure 4. Updating the Running Horizon (The Effect of the Maximum Interrupt Projected to the Target Position)

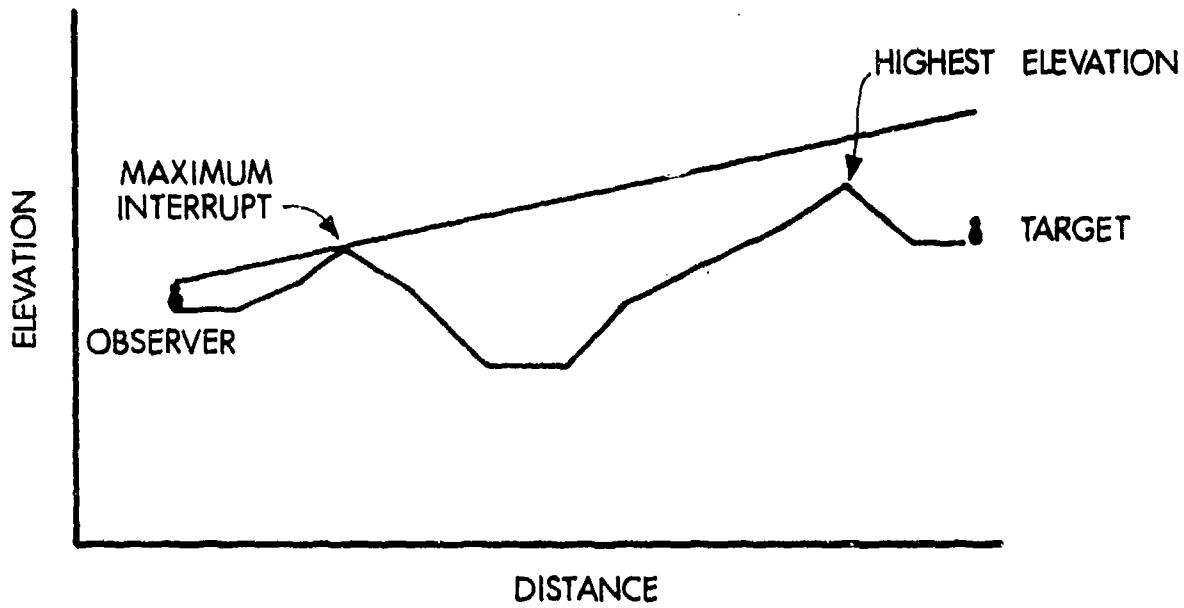

Figure 5. Maximum Interrupt Not Always Highest Elevation.

B. Full Map.

(1) Radial Map. Now how can this one-dimensional algorithm be expanded to two dimensions? One approach would be to produce a radial line-of-sight map, extending many profiles out from the observer. Certainly if line-of-sight information can be produced for one ray as described in the previous section, it would be a simple matter to project rays from the observer at small equally-space angle increments, combine the results and produce a two-dimensional map. With this method, however, the line-of-sight information would be very closely spaced near the observer and more widely spaced farther from the observer. As the profiles got further apart the likelihood of missing an important terrain feature would increase. Assuming, then, that evenly spaced data is more desirable, another method must be devised to produce the two-dimensional maps.

(2) Rectangular Map. As in the ray method the approach will be to work from the observer out (i.e., from the observer eastward, then from the observer westward), keeping track of a running horizon. But this time instead of having a running horizon point, there will be a south-to-north string of running horizon points (a horizon scanline) sweeping outward from the observer as the calculations are performed.

Remember, the map is actually a lattice of target spots. The goal is to determine for each target spot the value that denotes how high a target must be to be seen. Let $HOWHI(i)$ be the height the i th target must be raised to be seen. If the target height is less than $HOWHI(i)$ it cannot be seen; otherwise it can. The following sections describe a method for obtaining $HOWHI(i)$'s. In order to reach this goal one must continually keep up with $HORIZON(i)$, the effect of the maximum interrupt encountered between the observer and the current target position.

Scans Closest to Observer

Because the plan is to work outward from the observer, the first step is to perform calculations for the two target scanlines closest to the observer. In checking for line of sight to the points on these scans, the first iterations of the east-running horizon and west-running horizon must also be formed. Figure 6 will help illustrate this procedure.

Consider the point 1R (as in Figure 6A). First determine how high a target must be to be seen at position 1R. There are obviously no terrain profile elevations between the observer and this point, so one might automatically say $\text{HOWHI}(1R) = 0$. But if forests and urban areas are to be considered a check must be made to determine whether such an obstacle is located at 1R. If so, $\text{HOWHI}(1R) = 0 + \text{HVEG}(1R)$ where HVEG is the height of the obstacle. If the target height is less than $\text{HOWHI}(1R)$, a target at 1R cannot be seen and the appropriate symbol must be plotted. But more must be done at this position. The running horizon value at 1R must be determined. The highest elevation (vegetation and urban included) encountered between the observer and 1R is simply the elevation at 1R (there are no elevations given elsewhere) plus the obstacle height at 1R. Thus, $\text{HORIZON}(1R) = E(1R) + \text{HVEG}(1R)$ where $E(1R)$ is the terrain elevation at 1R. A similar procedure for position 1L results in $\text{HOWHI}(1L) = 0 + \text{HVEG}(1L)$ and $\text{HORIZON}(1L) = E(1L) + \text{HVEG}(1L)$.

Now consider the point 2R (as in Figure 6B). Determine the maximum elevation encountered between the observer and position 2R. This is the horizon value at (X, Y) , i.e., Z, where Z is the linear interpolation between the horizon at 1L and the horizon at 1R (See Appendix B1 for a discussion of the calculation of X, Y, & Z). Now project this Z value to the position 2R, obtaining $Z'(2R)$ (as described in Appendix B2). In order to be seen, the target point must be higher than $Z'(2R)$, so $\text{HOWHI}(2R) = Z'(2R) - E(2R)$. In addition the vegetation must be considered. To guarantee the target is above the ground $\text{HOWHI}(2R)$ must be the maximum of either $\text{HVEG}(2R)$ or $Z'(2R) - E(2R)$. Once HOWHI is determined the proper symbol is plotted for this point. Now the horizon at 2R must be computed. The horizon will simply be the maximum of (the projection of the old horizon to 2R) and (the current elevation, vegetation/urban included).

That is, $\text{HORIZON}(2R) = \text{MAX}(Z'(2R), E(2R) + \text{HVEG}(2R))$

Similarly, $\text{HOWHI}(2L) = \text{MAX}(Z'(2L) - E(2L), \text{HVEG}(2L))$

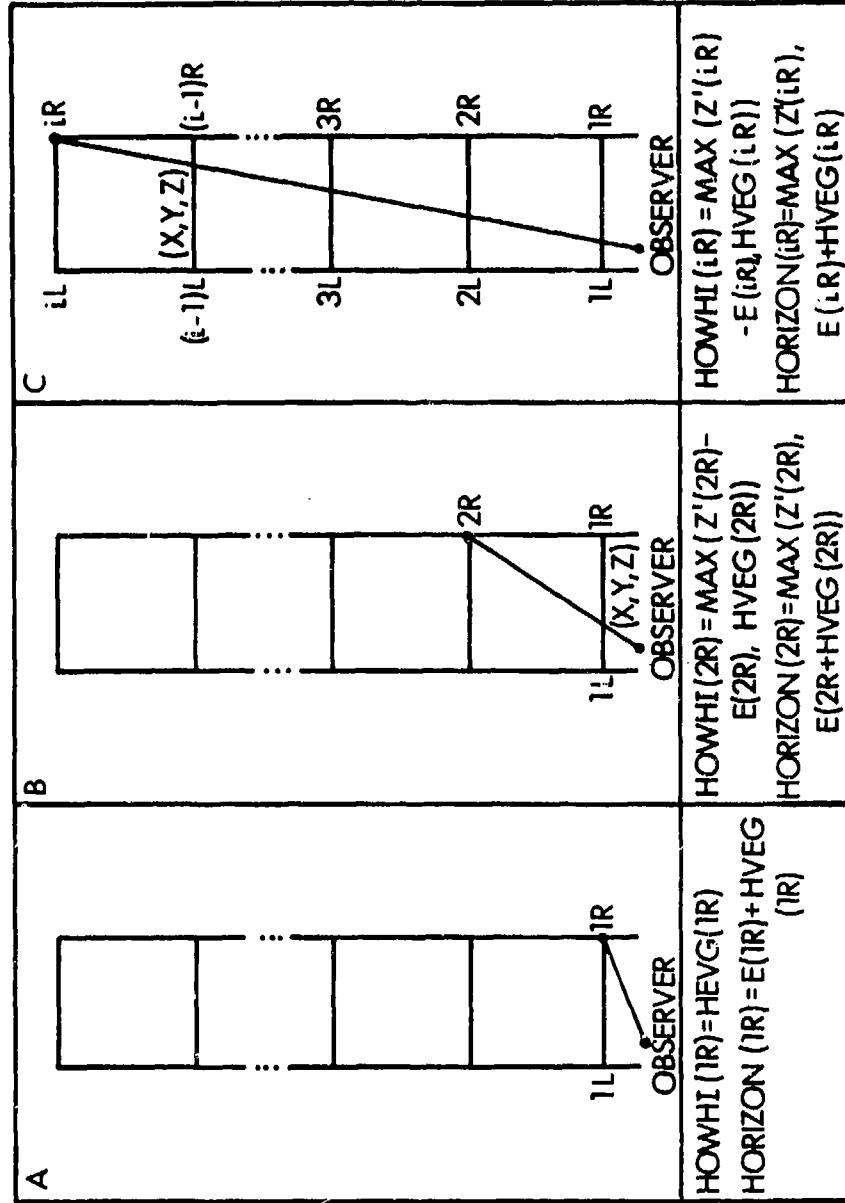

and $\text{HORIZON}(2L) = \text{MAX}(Z'(2L), E(2L) + \text{HVEG}(2L))$.

In general, for the i th point above the observer (See Figure 6C)

$\text{HOWHI}(i) = \text{MAX}(Z'(i) - E(i), \text{HVEG}(i))$

and $\text{HORIZON}(i) = \text{MAX}(Z'(i), E(i) + \text{HVEG}(i))$.

Points south of the observer should be handled in a manner similar to those north of the observer, resulting in identical equations for $\text{HOWHI}(i)$ and $\text{HORIZON}(i)$.

- = TARGET POSITION

iL = i th POSITION ON LEFT SCAN
 iR = i th POSITION ON RIGHT SCAN
 $E(iL)$ = DMA ELEVATION AT iL
 $Z'(iL)$ = PROJECTION OF Z TO TARGET POSITION iL
 $\text{HVEG}(iL)$ = VEGETATION/URBAN HEIGHT AT iL

Figure 6. Calculation of HOWHI and HORIZON for Scans Closest to the Observer.

Scans East of Observer

Consider scanline R_2 in Figure 7A, consisting of points $(...OR_2, 1R_2, 2R_2, 3R_2, \dots(n=1)R_2, nR_2)$. In order to obtain HOWHI's for this line, only the horizon values for scanline R and the terrain elevations for Scanline R_2 are needed. Working upward from the observer, the first target point to consider is $1R_2$. Check the terrain elevation at $1R_2$. This must be compared with the effect of the maximum interrupt encountered earlier (the horizon effect). The intersection of the observer-target line with the line of known horizon values closest to the target is at (X,Y) . A linear interpolation between $HORIZON(1R)$ and $HORIZON(OR)$ will provide Z, the horizon height at (X,Y) . Project Z to $1R_2$, obtaining $Z'(1R_2)$. Then

$$HOWHI(1R_2) = \text{MAX}(Z'(1R_2) - E(1R_2), HVEG(1R_2))$$

and $HORIZON(1R_2) = \text{MAX}(Z'(1R_2), E(1R_2) + HVEG(1R_2))$.

Similarly, using Figure 7B, the appropriate values for point $2R_2$ can be determined.

Figure 7C depicts a variation in this method. The observer-target line intersection with the line of known horizon values closest to the target is not along line R, but rather at a point (X,Y) between target points $2R$ and $2R_2$. In this case the HOWHI and HORIZON equations are as follows:

$$HOWHI(3R_2) = \text{MAX}(Z'(3R_2) - E(3R_2), HVEG(3R_2))$$

$$HORIZON(3R_2) = \text{MAX}(Z'(3R_2) + E(3R_2) + HVEG(3R_2))$$

Thus the intersection of the observer-target line with the closest vertical horizon scan line is not necessarily the intersection of interest. The explanation in Appendix B1 for deriving X, Y and Z takes both of the cases into account.

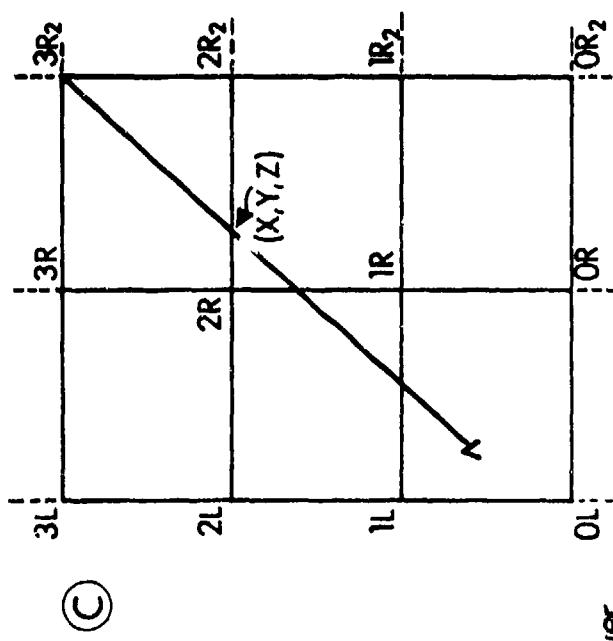

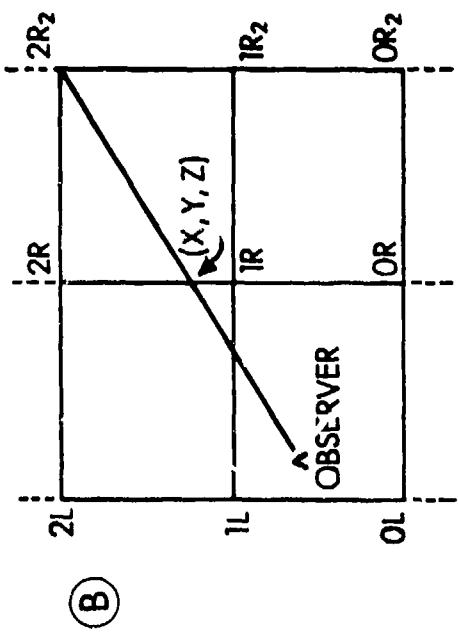

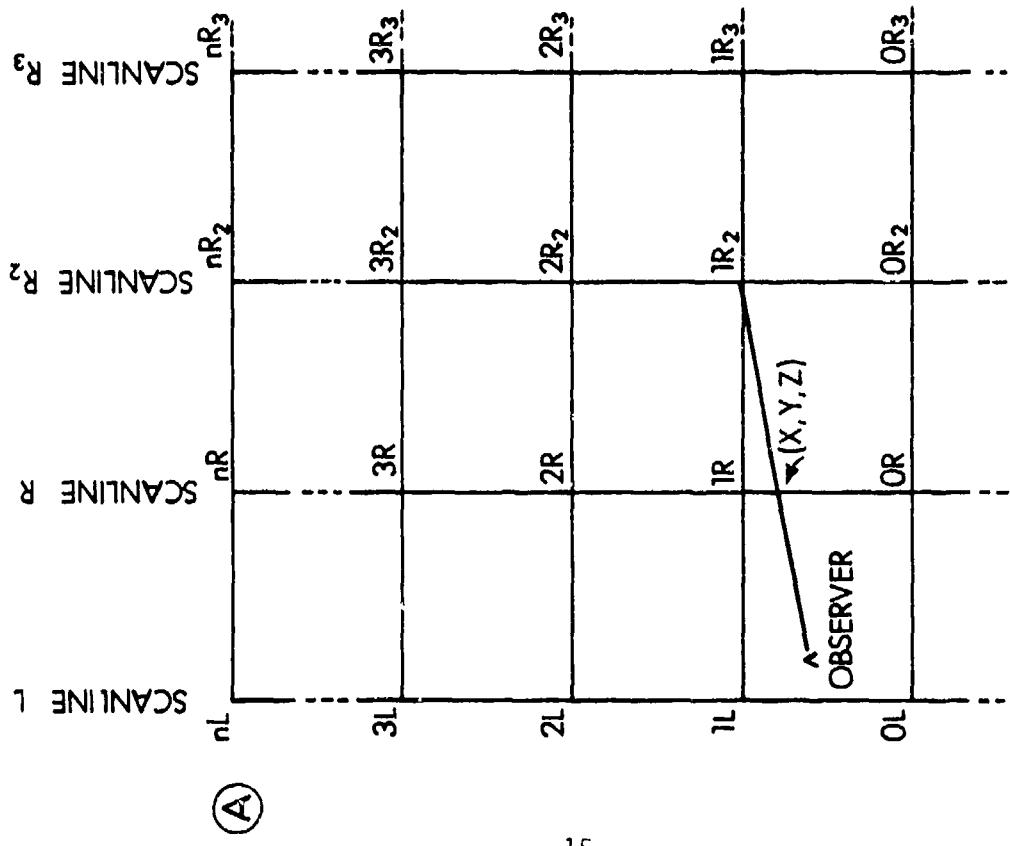

Figure 7. Calculations for Scans East of the Observer.

Scans West of Observer

In general, for points east of the observer

$$\text{HOWHI}(i) = \text{MAX } (Z'(i) - E(i), \text{HVEG}(i))$$

$$\text{HORIZON}(i) = \text{MAX } (Z'(i), E(i) + \text{HVEG}(i))$$

By simply reversing directions and starting with the horizon values corresponding to scanline L (calculated while working with scans closest to the observer) the same equations are found to apply to points west of the observer. Variations in the computation of values (X,Y,Z) in determining horizon effects are all accounted for in Appendix B1.

Algorithm Outline

In short, the map can be thought of as a lattice of equally spaced target positions. These are the points for which terrain elevations are available and can be thought of as south-to-north strings of target positions, or target scanlines. The following provides a general outline of the flow of the algorithm:

FIND AND PLOT LINE OF SIGHT INFORMATION FOR SCANS CLOSEST TO OBSERVER, WHILE CREATING ORIGINAL HORIZONS EAST AND WEST OF OBSERVER.

FOR SCANS FROM OBSERVER TO SIDE BOUNDARY (FIRST EASTWARD THEN WESTWARD DO:

READ ELEVATIONS FOR SCAN OF INTEREST

FOR POINTS FROM OBSERVER NORTH THEN FROM OBSERVER SOUTH DO:

FIND INTERSECTION OF OBSERVER-TARGET LINE WITH HORIZON LINE CLOSEST TO TARGET

INTERPOLATE BETWEEN KNOWN HORIZON VALUES TO OBTAIN HORIZON VALUE

PROJECT HORIZON VALUE TO CURRENT TARGET POSITION (TAKING INTO ACCOUNT THE EFFECT OF EARTH CURVATURE)

COMPARE CURRENT ELEVATION WITH PROJECTED HORIZON TO DETERMINE WHETHER LINE OF SIGHT EXISTS

UPDATE HORIZON VALUE

PLOT RESULTS

STOP

3.2 Solution to Storage and Compute Time Problem.

A. Storage. The savings in storage requirements for the SEE-FAR algorithm are considerable. The profile algorithm required all the elevation data to be easily accessible, since many scans of data were needed to produce each profile; the newer algorithm needs only the current scanline of elevation data and the most recently updated horizon information to perform the necessary computations. The amount of random access memory required, then, is a function of the north-to-south dimension of the map rather than the area of the map. A map that is 100 x 50 kilometers in size would take no more main memory than a map 1 x 50 kilometers, given equal grid size. The original algorithm would have taken 100 times more storage. Maps that would have been virtually impossible with the old algorithm are now quite possible. But if only storage requirements are reduced, the reader may wonder whether the machine time requirements would be prohibitive for production of these larger maps. The savings in computing time resulting from this approach must be considered.

B. Computing Time. As mentioned earlier, the original algorithm required on the order of n^3 operations for an $n \times n$ sized map, because each profile consists of many points, and each of these points might have to be considered in a single line-of-sight calculation. The newer algorithm, however, simply compares the current target elevation with the horizon effect at the target point. Thus, a small fixed number of calculations are required for each target point on the map. This algorithm is, then, of the order n^2 for an $n \times n$ map. For maps of larger sizes the computing time savings will be considerable. It can in many instances be the difference between a map reasonably produced and one so expensive in computation cost that its value to the tactician or analyst cannot outweigh the expense. Note that since n^2 target points are involved in an $n \times n$ map, order n^2 is the minimum possible complexity. A few examples of these differences are discussed in the following section.

4. COMPARISON OF MAPS RESULTING FROM EACH ALGORITHM

4.1 Discussion. The LOSMAP and SEE FAR algorithms discussed are quite different in nature. While each uses a method of linear interpolation to get results, the intuitive method interpolates between known elevations to get elevations along a profile, then checks to see if those elevations interrupt line of sight. The dynamic programming approach, on the other hand, keeps up with the effect of maximum interrupts encountered via the horizon array. A linear interpolation is made between horizon values to find a projection of the horizon to a specific target point. It is not surprising to discover the results of these methods are not always the same. But, while the "intuitive" LOSMAP method described uses interpolation and is therefore not an exact solution to the line of sight problem, it would be disappointing to find large discrepancies in the results of the two approaches. One would certainly hope the results of a new approach would conform somewhat to those of an intuitive method.

As it turns out, the results are quite similar. In fact, very close inspection is generally required to distinguish differences in line-of-sight maps with one target height. It is easier to detect differences when multiple target heights are used. The SEE FAR approach might at one time indicate a target visible that the LOSMAP approach indicated nonvisible. Another time the reverse situation might occur. In general, however, the boundaries of in-view and out-of-view areas do not differ widely between algorithms. It should be added that, while the dynamic programming approach may not be the first to come to mind when tackling the line-of-sight problem, it is a reasonable approach, one certainly not counter to intuition. And the savings in time and storage cannot be ignored.

4.2 Sample Maps. The following pages will provide the reader an opportunity to compare the results of the two algorithms.

5. SUMMARY

5.1 Advantages of the SEE FAR Algorithm. The SEE FAR algorithm, then, provides a method for generating line-of-sight maps (and thereby obtaining intervisibility data) for a much larger area or for a smaller grid than could reasonably be provided using the LOSMAP algorithm. This dynamic programming approach results in an order of complexity of n^2 for an $n \times n$ map, which is the minimum that can be expected. Further, it reduces the storage requirements such that only one scanline of elevation data need be in memory at any one time. Thus, it is an order of magnitude better than the LOSMAP algorithm in both time and storage requirements.

5.2 The SEE FAR Program. Appendix A1 contains a copy of the SEE FAR program, an implementation of the algorithm discussed in this report. It should be noted that the algorithm discussion is concerned with the basic approach to the line-of-sight problem. The SEE FAR program has several embellishments. First, if an observer is in a forest/urban area, and the proper option is selected, SEE FAR will attempt to move the observer out of the obstruction. Second, the ratio of visible-to-total targets in a selected area of interest is given. Third, terrain data on as many as 12 DMA tapes can be merged and put into a direct access file. Finally, the HOWHI array, which indicates for every target position how high the target must be raised to be seen by the selected observer, can be saved on a permanent file. This allows one, through short fast-running programs, to vary target heights or merge line of sight data for several observers obtaining maps which indicate areas visible to m-out-of-n observers ($1 \leq m \leq n$). These m-out-of-n maps, or composite maps, are done by a separate program now, but could easily be provided via the SEE FAR program.

5.3 Problems Remaining. There are line-of-sight data requirements for which SEE FAR does not seem a viable alternative. For example, the LOSPATH program, in use at AMSAA, checks along paths for line of sight. To use SEE FAR for this problem one must generate a rectangular map containing all the path points and then check for line of sight at appropriate points within the rectangle. Because SEE FAR builds on information generated for all the points between the observer and the current target position, it does not seem optimal when target points are in scattered positions rather than at evenly spaced intervals within a rectangle of interest.

The question of how much discrepancy to expect between the LOSMAP and SEE FAR algorithms has not been determined analytically. This may be of interest; but since each approach provides an interpolated approximation to the line-of-sight problem, the value of such an analysis is questionable.

SUBROUTINE XPOSIT(X,Y,ICARE)

C ***
C BY ARTHUR GROVES
C THE PURPOSE OF THIS SUBROUTINE IS TO ATTEMPT TO MOVE AN OBSERVER
C AT (X,Y) WHICH IS IN VEGETATION/URBAN TO A NEARBY POSITION WHICH
C IS IN THE OPEN. TO HAVE IT DO THIS, CALL THE SUBROUTINE WITH
C ICARE=0.1 IT THEN LOOKS AT THE ELEVATIONS AT THE FOUR CORNERS OF
C THE SQUARE OF ELEVATIONS (X,Y) IS IN. IF NONE OF THESE ARE
C WOODED/URBAN, IT RETURNS THE ORIGINAL (X,Y). IF ALL FOUR CORNERS
C ARE WOODED/URBAN, OR IF EXACTLY ONE PAIR OF OPPOSITE CORNERS ARE
C WOODED/URBAN, IT PRINTS AN APPROPRIATE STATEMENT AND STOPS THE
C RUN, MAKING NO ATTEMPT TO FIND AN OPEN NEARBY LOCATION. IF ONE,
C TWO (ADJACENT) OR THREE CORNERS ARE WOODED/URBAN, IT MOVES THE
C OBSERVER THE LEAST POSSIBLE DISTANCE TO AN ADJACENT SQUARE NOT
C KNOWN TO HAVE ANY WOODED/URBAN CORNERS. IF THIS NEW SQUARE IN
C FACT HAS NO WOODED/URBAN CORNERS, IT RETURNS AS (X,Y) THE NEW
C ADJUSTED OBSERVER LOCATION AND PRINTS THE NEW LOCATION. IF THIS
C NEW SQUARE DOES HAVE ONE OR MORE WOODED/URBAN CORNERS, IT PRINTS
C THAT IT MADE AN UNSUCCESSFUL ATTEMPT TO MOVE THE OBSERVER AND
C THEN STOPS THE RUN. IF THE SUBROUTINE IS CALLED WITH ICARE=1,
C THIS ENTIRE PROCEDURE IS BYPASSED AND (X,Y) IS RETURNED UNCHANGED
C WHETHER OR NOT VEGETATION OR URBAN ARE PRESENT.
C ***

Appendix B1

Calculation of Critical Horizon Coordinates

In determining whether a target position is in-view or out-of-view the first step is to consider the effect of intervening terrain. This is done by finding where the observer-target line intersects the closest line of known horizon values (as illustrated in Figure B1-1). This intersection location is referred to as (X, Y) . To find the horizon value, Z , at (X, Y) , one need only interpolate between the closest horizon values on the horizon scan, pictured as Z_1, Z_2 .

The problem of solving for X, Y , and Z breaks into eight cases (illustrated in Figure B1-2). These cases are determined by the relationship between the coordinates of the target and those of the observer.

Considering a pair of axes with origin at the observer position, each quadrant has been divided into two sectors. Targets in one sector have an observer-target line slope whose absolute value is less than or equal to one. In the other sector the absolute value of this slope is greater than one. The reason for this division will be explained by the following two examples.

Selecting quadrant 1, X , Y , and Z will be determined for the area where $XTGT \geq XOBS$, $YTGT \geq YOBS$ and $(XTGT - XOBS) \geq (YTGT - YOBS)$. (See Figure B1-3.)

Letting GRID be the grid of the map data $X = XTGT - GRID$, since the horizon is one scan away. Knowing X , we can solve for Y from the equation of the observer-target line:

$$Y = \frac{(YTGT - YOBS)}{(XTGT - XOBS)} (XTGT - XOBS - GRID) + YOBS.$$

It remains to solve for Z . Consider the target to be the $ITGT^{th}$ position on a scan and ZOLD to be an array containing old horizon values.

Let $DX = XTGT - XOBS$ and $DY = YTGT - YOBS$.

Then linearly interpolating,

$$Z = (1 - \frac{DY}{DX}) ZOLD (ITGT) + (\frac{DY}{DX}) ZOLD (ITGT-1)$$

Now consider a target in the upper portion of quadrant 1, where $XTGT \geq XOBS$, $YTGT \geq YOBS$ and $(XTGT - XOBS) < (YTGT - YOBS)$. See Figure B1-4. In this example the closest line of known horizon values is formed by ZOLD (ITGT-1) and ZLATER (ITGT-1) rather than by two old horizon values. In this case

$$Y = YTGT - GRID$$

$$X = \frac{DX (DY - GRID)}{DY} + XOBS$$

$$Z = (1 - \frac{DX}{DY}) ZLATER (ITGT-1) + (\frac{DX}{DY}) ZOLD (ITGT-1)$$

Where DX , DY and $GRID$ are as defined in the previous example. Similarly, equations for X , Y , and Z may be derived for each of the eight sectors, as indicated in Figure B1-5.

| 4D DX>0 DY<0 DX<-DY | $\frac{DX(DY+GRID)}{DY} + X_{OBS}$ | YTGT + GRID | $(1 + \frac{DX}{DY}) ZLATER(ITGT+1)$ $- (\frac{DX}{DY}) ZOLD(ITGT+1)$ |

(XTGT, YTGT) = THE TARGET COORDINATES
 (XOBS, YOBS) = THE OBSERVER COORDINATES
 GRID = MAP GRID
 DX = XTGT - XOBS
 DY = YTGT - YOBS
 ZLATER = ARRAY HOLDING HORIZON REPRESENTING PREVIOUS ELEVATION
 ZOLD = FUTURE HORIZON VALUES CALCULATED FOR CURRENT SCAN

Appendix 82

In Appendix B1, a method was shown for calculation of x , y , and z , where (x, y) is the intersection of the observer-target line with the last running horizon line and z is the horizon elevation at the position (x, y) . This Appendix describes the method for projecting the horizon elevation to the target position. It is at this time that earth curvature is introduced into the line of sight calculations.

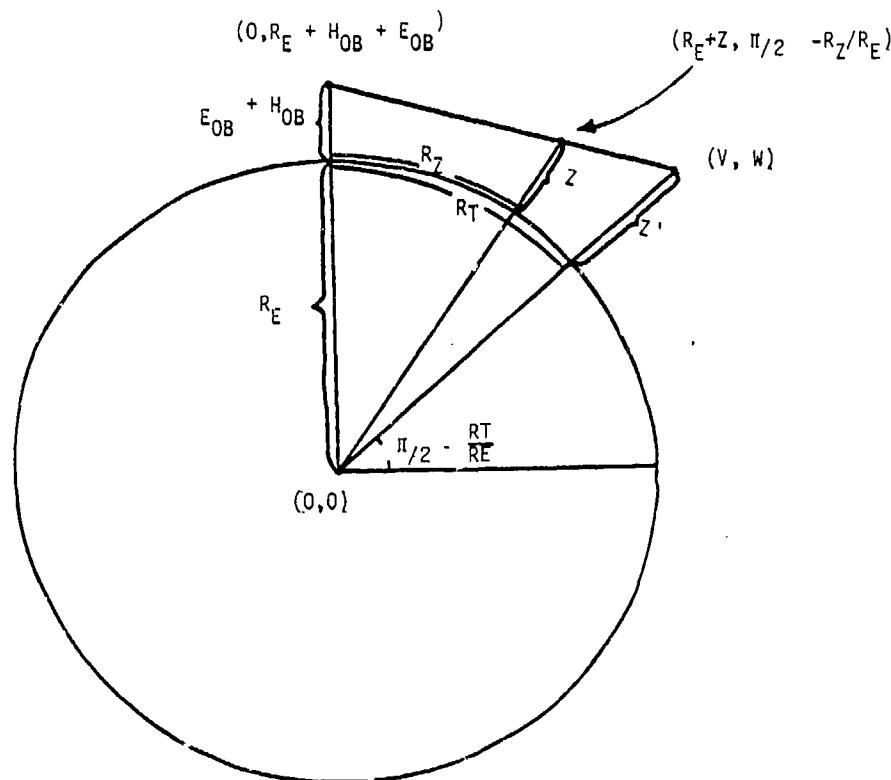

Letting R_E = the radius of the earth

E_{OB} = the elevation of the observer

H_{OB} = the height of the observer

R_Z = the range to the horizon line from the observer

and R_T = the range to the target from the observer
the situation might be drawn as follows:

Now

$$Z' = \sqrt{V^2 + W^2} - R_E$$

so if we can determine values V and W, we can find Z'.

But (V,W) is simply the intersection of lines $(0,0) - (V,W)$ and $(0, R_E + H_{OB} + E_{OB}) - (V, W)$.

The equation for $(0,0) - (V,W)$ is

$$Y' = AX' + B$$

where

$$B = 0$$

$$A = \tan(\pi/2 - (\frac{R_T}{R_E})) = \cot(\frac{R_T}{R_E})$$

And the equation for line $(0, R_E + H_{OB} + E_{OB}) - (V, W)$ is

$$Y' = A'X' + B'$$

where

$$B' = R_E + H_{OB} + E_{OB}$$

and

$$A' = \frac{(R_E + Z) \cos(\frac{R_Z}{R_E}) - (R_E + H_{OB} + E_{OB})}{(R_E + Z) \sin(\frac{R_Z}{R_E})}$$

Solving these two line equations simultaneously, then, for V and W

$$V = \frac{B'}{\cot(\frac{R_T}{R_E}) - A'}$$

$$W = \frac{\cot(\frac{R_T}{R_E}) B'}{\cot(\frac{R_T}{R_E}) - A'}$$

with A' and B' as defined above.

APPENDIX C

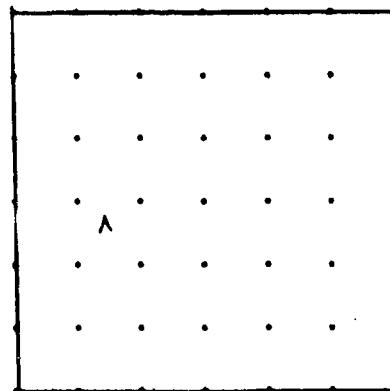

LOSMAP TIME COMPLEXITY

C-1

The next page is blank.

APPENDIX C 1

The Time Complexity for an NXN Map Using the LOSMAP Algorithm

Consider a Map with N scan lines, and N points per scan line and an observer at a point such than n scan lines are to his "left" and m points on each scan are below him.

In example above, N = 7

$$n = 2$$

$$m = 3$$

If a calculation has to be made each time a profile crosses either a vertical or horizontal scan line, how many calculations have to be made to compute a LOSMAP?

There are N-n scan lines to the right of the observer. The first one (the one immediately to the observer's right) requires N crossings of vertical scan lines (one for each point on the scan); the second requires 2N crossings of vertical scan lines, etc. for a total number of crossings of

$$\begin{aligned} & N + 2N + 3N + \dots + (N-n) N \\ &= N \{1 + 2 + 3 + \dots + (N-n)\} \\ &= N \frac{(N-n)(N-n+1)}{2} \end{aligned}$$

There are n scan lines to the left of the observer.

The total number of crossings of these is

$$\begin{aligned} & N + 2N + \dots + n N \\ &= N (1+2+\dots+n) \\ &= N \frac{n(n+1)}{2} \end{aligned}$$

Therefore the total number of crossings of vertical scan lines is

$$\begin{aligned}n_v &= \frac{N}{2} \{(N-n)(N-n+1) + n(n+1)\} \\n_v &= \frac{N}{2} \{N^2 - nN + N - nN + n^2 - n + n^2 + n\} \\&= \frac{N}{2} \{N^2 + N + 2n^2 - 2nN\} \\&= \frac{N}{2} \{N^2 + N + 2n(n-N)\}\end{aligned}$$

Now $2n(n-N)$ is most negative when $n = N/2$,

Since $f(n) = 2n^2 - 2nN$

$$f'(n) = 4n - 2N$$

$$\text{Setting } 4n - 2N = 0, n = \frac{N}{2}$$

So $f(n)$ has its minimum or maximum at $N/2$

But $f''(N/2) = 4 > 0$ so $f(n)$ is minimal when $n = N/2$.

$$\begin{aligned}\text{So } n_v &\geq \frac{N}{2} \{N^2 + N + 2(\frac{N}{2})(-\frac{N}{2})\} \\&\geq \frac{N}{2} \{N^2/2 + N\} \\&> N^3/4 + N^2/2, \text{ order } N^3\end{aligned}$$

We have only looked at vertical scan lines. There are as many again crossings of horizontal scan lines, (similar analysis using m in place of n). This essentially doubles the number of calculations, but it still remains of order N^3 for a map with minimum crossings; that is, of order $\underline{N^3}$.

There are always less than $2N$ crossings (horizontal and vertical) for each of the N^2 target positions, so the order is $\underline{N^3}$.

Therefore the order is N^3 for the LOSMAP algorithm.
